A set of new, precise data have recently been made available by the NA49 Collaboration for charged pion production in proton-proton and proton-Carbon reactions at 158 GeV. The current paper compares this new data to five currently available arithmetic parameterizations. Although a precise fit is not expected, two of the parameterizations do not work very well but the other three are able to provide a moderately good, but not precise fit to the proton-proton data. The best two of these three parameterizations are scaled to the proton-Carbon data and again provide a moderately good, but not precise fit.

I. INTRODUCTION

The NA49 Collaboration [1,2] has recently completed a series of measurements for charged pion production in proton-proton (pp) and proton-Carbon (pC) collisions at a beam momentum of 158 GeV, corresponding to $\sqrt{s} = 17$ GeV. This surpasses previous data in that the new data is of much higher precision and quality and can therefore be used to provide more precise tests of hadronic production models. The NA49 Collaboration [1,2] indicate that simple arithmetic parameterizations are unable to account for the fine structure seen in their data, and they therefore provide a numerical interpolation scheme. We agree with this. However arithmetic parameterizations are used in a wide variety of applications including simulation of particle physics experiments [3], simulations of cosmic rays showers in the Earth atmosphere [4–6], description of particle reactions relevant to astrophysics [7] and predicting radiation environments inside spacecraft [8]. For those using such parameterizations it is of interest to know how they compare to the new precision NA49 data [1,2], even though a precision fit will not be possible. Blattnig, Swaminathan, Kruger, Ngom, and Norbury [9] analyzed a set of parameterizations currently available and compared to an extensive data set for both neutral and charged pion production in pp collisions. It was concluded that the parameterization of Badhwar and Stephens [10] provided the best overall description of charged pion production. It is interesting to see how this compares to the new data [1].

The Blattnig *et al.* parameterizations [9] have also been used in a variety of astrophysical and astroparticle applications [11–17] where the interest is in calculating the spectrum of gamma rays, electrons and neutrinos which result from the decay of pions produced in proton-proton interactions. For example, Bernado [11] used the high

energy $pp \rightarrow \pi^0$ cross sections in order to calculate the γ -ray spectrum from microquasars. This spectrum can be measured using gamma ray telescopes on satellites. Pion production cross section parameterizations [9] have also been used recently in nuclear and particle physics applications [18–21]. The nuclear modification factor R_{AA} is basically the ratio of a nucleus-nucleus cross section divided by a scaled nucleon-nucleon cross section. The behavior of R_{AA} can be used to provide information on signatures of quark-gluon plasma formation [18–21]. Pion parameterizations have been used for the proton-proton cross sections in these nuclear modification factors [18–21]. Given such widespread use of pion production cross section parameterizations, we deem it worthwhile to test currently available parameterizations against new accelerator data. This is the aim of the present work.

The outline of the paper is as follows. We summarize the parameterizations studied previously [9] making note of necessary variable transformations needed to describe the NA49 [1,2] data set. We then compare these parameterizations to the new data for pp reactions. Therefore the present work is a continuation of the previous paper [9] but applied to the new data. The parameterizations which are able to give a reasonable fit to the pp data are then scaled and compared to the pC data.

II. DIFFERENTIAL CROSS SECTIONS

A. Review of kinematics

Consider the *inclusive* reaction

$$a + b \rightarrow c + X, \quad (1)$$

where c is the produced particle of interest and X is anything. Throughout this paper we assume that all variables, such as all momenta, are evaluated in the center of momentum (CM) frame. The momentum of particle c is denoted as p , and supposing that it comes out at angle θ

*Electronic address: john.norbury@usm.edu

†Electronic address: ltownsen@tennessee.edu

to the beam direction, then the longitudinal and transverse components of momentum are

$$p_z \equiv p \cos\theta, \quad (2)$$

$$p_T \equiv p \sin\theta. \quad (3)$$

Feynman used a scaled variable instead of p_z itself [22–25]. The *Feynman scaling variable* is [24,26–31]

$$x_F \equiv \frac{p_z}{p_{z\max}}, \quad (4)$$

where p_z is the longitudinal momentum of the produced meson in the CM frame, and $p_{z\max}$ is the maximum momentum of the produced meson given by [27,28,31]

$$p_{z\max} = \sqrt{\frac{\lambda(s, m_c, m_X)}{4s}} \quad (5)$$

with

$$\lambda(s, m_i, m_j) \equiv (s - m_i^2 - m_j^2)^2 - 4m_i^2 m_j^2. \quad (6)$$

Note that

$$p_{z\max} = p_{\max}. \quad (7)$$

Nagamiya and Gyulassy [28] point out that if c is a boson with zero baryon number, then

$$m_X = m_A + m_B \quad (8)$$

in agreement with the $p_{z\max}$ formulas of Nagamiya and Gyulassy [28] and Cassing [31]. The Feynman scaling variable approaches the limiting value [29]

$$x_F \rightarrow \frac{2p_z}{\sqrt{s}} \quad \text{as } s \rightarrow \infty. \quad (9)$$

Also it is obviously bounded in the following manner [24]:

$$-1 < x_F < 1. \quad (10)$$

Sets of variables that are often used are either (p, θ) or (p_z, p_T) . Writing

$$p_z = x_F \sqrt{\frac{\lambda(s, m_c, m_X)}{4s}} \quad (11)$$

shows that another useful and common variable set is (x_F, p_T) , which is used by the NA49 Collaboration [1,2] in presenting their data. These variables are also used throughout the present work. Rapidity is defined as

$$y = \frac{1}{2} \log\left(\frac{E + p_z}{E - p_z}\right) \quad (12)$$

so that

$$E = m_T \cosh y, \quad (13)$$

$$p_z = m_T \sinh y, \quad (14)$$

where the transverse mass is defined through

$$m_T^2 = m^2 + p_T^2 = E^2 - p_z^2 \quad (15)$$

with m as the mass of the produced particle c . This gives yet another useful variable set (y, p_T) . In the work below it will be necessary to write the rapidity in terms of the Feynman scaling variable as

$$y = \frac{1}{2} \log\left(\frac{\sqrt{x_F^2 + m_T^2/p_{z\max}^2} + x_F}{\sqrt{x_F^2 + m_T^2/p_{z\max}^2} - x_F}\right). \quad (16)$$

For massless particles, $E = p$, so that y becomes

$$\eta = \frac{1}{2} \log\frac{1 + \cos\theta}{1 - \cos\theta} = -\log\left(\tan\frac{\theta}{2}\right). \quad (17)$$

This is called the pseudorapidity and is a good approximation to the rapidity for particles moving near the speed of light. Because the pseudorapidity depends only on angle it can be used as an angular variable. Wong [27] provides useful formulas involving η and also gives expressions relating y to η for slower-than-light particles.

B. Parameterizations

Blattnig *et al.* [9] did a study of the various parameterizations available for inclusive pion production in proton-proton collisions. They concluded that the Badhwar parameterization [10] worked the best for charged pion production. However other parameterizations [9,32–35] will be reviewed again to see which works best for the new experimental data. The NA49 data set [1,2] uses the variables (x_F, p_T) , whereas some of the parameterizations below are written in terms of other variables sets. These will need to be converted to (x_F, p_T) .

1. Badhwar parameterization

This parameterization [10] gives the Lorentz-invariant differential cross section as

$$E \frac{d^3\sigma}{d^3p} = \frac{A}{(1 + 4m_p^2/s)^r} (1 - \tilde{x})^q \exp\left[\frac{-Bp_T}{1 + 4m_p^2/s}\right], \quad (18)$$

where m_p is the proton mass, $\sqrt{s}$ is the total energy in the center of momentum (CM) frame, and p_T is the transverse momentum of the produced meson in the CM frame. The other terms are given by

$$\tilde{x} = \left[x_F^2 + \frac{4}{s}(p_T^2 + m_\pi^2)\right]^{1/2}, \quad (19)$$

where it is assumed that the variables appearing in x_F are in the CM frame. Badhwar writes $x_{\parallel}^* \equiv x_F$. Also

$$q = \frac{C_1 + C_2 p_T + C_3 p_T^2}{\sqrt{1 + 4m_p^2/s}}. \quad (20)$$

The constants are listed in Table I. The Badhwar variables

TABLE I. Constants for the Badhwar parameterization. Units for A , C_2 and C_3 are mb/GeV^2 , GeV^{-1} , and GeV^{-2} respectively, and other constants are dimensionless.

Particle	A	B	r	C_1	C_2	C_3
π^+	153	5.55	1	5.3667	-3.5	0.8334
π^-	127	5.3	3	7.0334	-4.5	1.667

are (x_F, p_T) , which are the variables used in the NA49 data set [1,2], so that no variable conversion is necessary.

2. Alper parameterization

The Alper [32] parameterization used in Ref. [9] was

$$E \frac{d^3\sigma}{d^3p} = A \exp(-Bp_T + Cp_T^2) \exp(-Dy^2), \quad (21)$$

where A , B , C , and D are constants that depend on the value of $\sqrt{s}$. A more general formula is [32]

$$E \frac{d^3\sigma}{d^3p} = A_1 \exp(-Bp_T) \exp(-Dy^2) + A_2 \frac{(1 - p_T/p_{\text{beam}})^m}{(p_T^2 + M^2)^n}. \quad (22)$$

The constants are listed in Table II. The Alper variables are (y, p_T) . To change to the variables (x_F, p_T) , we convert the rapidity in Eq. (22) to x_F using (16).

3. Ellis parameterization

The Ellis [33] parameterization is

$$E \frac{d^3\sigma}{d^3p} = A(p_T^2 + M^2)^{-N/2} (1 - x_T)^F, \quad (23)$$

where A is an overall normalization fitted to be $A = 13$ in reference [9] and $x_T \equiv p_T/p_{\text{max}} \approx 2p_T/\sqrt{s}$. The same value of A is used in the present work. The other constants are listed in Table III. The Ellis parameterization is independent of the emission angle θ , and so does not carry any dependence on p_z , x_F , y etc.

4. Mikhov parameterization

The Mikhov [34] parameterization is

$$E \frac{d^3\sigma}{d^3p} = A \left(1 - \frac{p}{p_{\text{max}}}\right)^B \exp\left(-\frac{p}{C\sqrt{s}}\right) V_1(p_T) V_2(p_T),$$

where

TABLE II. Constants for the Alper parameterization.

Particle	A_1	B	D	A_2	M	m	n
π^+	210	7.58	0.20	10.7	1.03	10.9	4.0
π^-	205	7.44	0.21	12.8	1.08	13.1	4.0

TABLE III. Constants for the Ellis parameterization.

Particle	N	M^2	F
π^+	7.70	0.74	11.0
π^-	7.78	0.79	11.9

TABLE IV. Constants for the Mikhov parameterization.

Particle	A	B	C	D	E	F
π^+	60.1	1.9	0.18	0.3	12	2.7
π^-	51.2	2.6	0.17	0.3	12	2.7

$$V_1(p_T) = (1 - D) \exp(-Ep_T^2) + D \exp(-Fp_T^2) \quad \text{for } p_T \leq 0.933 \text{ GeV}$$

$$= \frac{0.2625}{(p_T^2 + 0.87)^4} \quad \text{for } p_T > 0.933 \text{ GeV}$$

and

$$V_2(p_T) = 0.7363 \exp(0.875 p_T) \quad \text{for } p_T \leq 0.35 \text{ GeV}$$

$$= 1 \quad \text{for } p_T > 0.35 \text{ GeV}.$$

The constants are listed in Table IV. Using $p = \sqrt{p_z^2 + p_T^2}$, gives the Mikhov variables (p_z, p_T) which are transformed to (x_F, p_T) using (11).

5. Carey parameterization

The Carey [35] parameterization, which only applies to π^- , is

$$E \frac{d^3\sigma}{d^3p}(\pi^-) = N(p_T^2 + 0.86)^{-4.5} (1 - x_R)^4, \quad (24)$$

where N is an overall normalization fitted to be $N = 13$ in reference [9] and $x_R \equiv p/p_{\text{max}} \approx 2p/\sqrt{s}$. The same value of N is used in the present work. The Carey variables are (p_z, p_T) . To change to the variables (x_F, p_T) , we use $x_R = \sqrt{x_F^2 + p_T^2}/p_{\text{max}}$.

III. COMPARISON TO DATA

The above parameterizations are compared to the new experimental data in Figs. 1–13.

A. Comparison to pp data

Positive pion production in pp reactions is shown in Figs. 1–4. In agreement with the conclusions of the NA49 Collaboration [1], none of these arithmetic parameterizations is able to account for all the fine structure seen in the data. The Badhwar, Alper and Ellis parameterizations are unable to reproduce the shape of the differential cross section at low p_T . The Alper and Ellis parameterizations

FIG. 1 (color online). π^+ production in pp collisions. Data from reference [1] is plotted against the parameterization of Badhwar [10]. The values of x_F from top to bottom are 0.0, 0.01, 0.02, 0.025, 0.03, 0.04, 0.05, 0.06, 0.07, 0.075, 0.08, 0.1, 0.12, 0.15, 0.2, 0.25, 0.3, 0.35, 0.45, 0.55. Following Ref. [1], data and lines are multiplied successively by 0.5 to allow for a better separation.

are unable to account for the data at larger values of x_F . However, on the positive side, the Mikhov parameterization (Fig. 4) does give a reasonable description of the shape at low p_T and the Badhwar parameterization (Fig. 1) gives a reasonable fit to the data over all x_F values for $p_T > 0.3$ GeV. In general, the Alper and Ellis fits are not good, but the Badhwar and Mikhov fits are moderately good, but certainly not precise.

Negative pion production in pp reactions is shown in Figs. 5–9. Again, in agreement with the conclusion of Ref. [1], none of these arithmetic parameterizations is able to account for all the fine structure seen in the data. The conclusions are the same as for positive pions production, except that the Badhwar parameterization now fails for larger values of x_F . The Carey parameterization is reasonable except for small values of x_F at low p_T . In

FIG. 2 (color online). π^+ production in pp collisions. Data from Ref. [1] is plotted against the parameterization of Alper [32]. Values of x_F and data and line multiplication are the same as Fig. 1.

general, the Alper and Ellis fits are not good, but the Badhwar, Mikhov, and Carey fits are moderately good, but not precise.

B. Comparison to pC data

Although the primary emphasis of this paper is on the pp reactions, nevertheless it is of interest to see if the pp parameterizations are able to scale to fit the new pC data [2], although a precise fit is not expected. We will only consider the parameterizations of Badhwar and Mikhov because they provided the best fits to the pp data.

One should note that in comparing to the pC data we will assume the same cross section for proton-proton and proton-neutron scattering. However, as shown in the paper by Pawlowski and Szczurek [36], this is known not to be true in general for the energy region of the new NA49 data. We justify our use of the same cross sections by noting the following. The data of Pawlowski and Szczurek [36] (see

FIG. 3 (color online). π^+ production in pp collisions. Data from Ref. [1] is plotted against the parameterization of Ellis [33]. Values of x_F and data and line multiplication are the same as Fig. 1.

their Fig. 2), show that these cross sections are significantly different only for $x_F < -0.05$. For $x_F > -0.05$ the cross sections are very similar and in fact for $x_F > 0$, Pawłowski and Szczurek [36] themselves state that $\sigma_{pp}^{\pi^+} \approx \sigma_{pn}^{\pi^+}$. In our comparisons, we show 25 different values of x_F . Only two of these, namely $x_F = -0.01$ and $x_F = -0.075$ are such that there is a significant difference between the proton-proton and proton-neutron cross section. For π^+ production the proton-proton cross section is about twice that of the proton-neutron cross section and vice versa for π^- [36]. This means that only for $x_F = -0.01$ and $x_F = -0.075$ our comparisons to data will be slightly worse for π^+ and slightly better for π^- . We now discuss various models.

The *wounded nucleon model* was introduced by Bialas, Bleszyński, and Czyż [37]. The number of wounded nucleons is simply the number of participants involved in the reaction. The main assumption is that the particle multi-

FIG. 4 (color online). π^+ production in pp collisions. Data from Ref. [1] is plotted against the parameterization of Mokhov [34]. Values of x_F and data and line multiplication are the same as Fig. 1.

licity is proportional to the number of wounded nucleons. Consider pA reactions. The incident proton interacts with ν nucleons in the target nucleus [38], which is some fraction of the total nucleon number A , and is determined from collision geometry and the hadron-nucleon cross section [38]. In a pA reaction, the number of participants is $(1 + \nu)$. Let N_{pA} be the multiplicity of particles of interest produced in the pA reaction, and let N_{pp} be the particle multiplicity in the pp reaction. For example this could be the number of pions produced in a reaction. The multiplicities are related by $N_{pA} = \frac{1}{2}(1 + \nu)N_{pp}$. The $\frac{1}{2}$ factor is there because the “nucleon-nucleon interaction requires two wounded nucleons” [39]. The following comes from reference [39]. For a nucleus-nucleus collision let A be the number of nucleons in the projectile and let B be the number of nucleons in the target. Then [39] $N_{AB} = \frac{1}{2}W_{AB}N_{pp}$ where W_{AB} is the number of participant nucleons, i.e. the “number of nucleons that have interacted at

FIG. 5 (color online). π^- production in pp collisions. Data from Ref. [1] is plotted against the parameterization of Badhwar [10]. The values of x_F from top to bottom are 0.0, 0.01, 0.02, 0.025, 0.03, 0.04, 0.05, 0.06, 0.07, 0.075, 0.08, 0.1, 0.12, 0.15, 0.2, 0.25, 0.3, 0.35, 0.45, 0.55, 0.65, 0.75, 0.85. Following Ref. [1], data and lines are multiplied successively by 0.5 up to $x_F = 0.35$ and by 0.75 for $x_F \geq 0.45$ to allow for a better separation.

least once” [39]. This is given by Ref. [39] $W_{AB} = A \frac{\sigma_{pB}}{\sigma_{AB}} + B \frac{\sigma_{pA}}{\sigma_{AB}}$, where σ_{pA} and σ_{pB} are the proton-nucleus inelastic cross sections and σ_{AB} is the nucleus-nucleus cross section given in reference [39]. If the projectile nucleus is actually a proton then $W_{pB} = \frac{\sigma_{pB}}{\sigma_{pB}} + B \frac{\sigma_{pp}}{\sigma_{pB}} = 1 + B \frac{\sigma_{pp}}{\sigma_{pB}}$ or $1 + \nu = W_{pA} = 1 + A \frac{\sigma_{pp}}{\sigma_{pA}}$ showing that [40] $\nu = A \frac{\sigma_{pp}}{\sigma_{pA}}$. In pA or AA collisions then the particle multiplicity scales with the number of wounded nucleons, which is often calculated with Glauber theory [41].

Instead of wounded nucleon or participant scaling, one can have *binary scaling*. The total number of produced particles in nuclear collisions comes from both soft and hard processes. Soft processes should scale with the number of participants and hard processes should scale [42]

FIG. 6 (color online). π^- production in pp collisions. Data from reference [1] is plotted against the parameterization of Alper [32]. Values of x_F and data and line multiplication are the same as Fig. 5.

with the average number of binary nucleon-nucleon collisions denoted as N_{coll} . Reference [43] contains a nice introduction to *hard processes*. For example, the PHENIX experiment [43] focuses on detecting large transverse momentum p_T particles that arise from the early stages of relativistic heavy ion collisions. In the early stage nucleon-nucleon collisions cause jet production resulting from hard parton collisions. The jets subsequently decay into high momentum hadrons with $p_T \sim 2$ GeV [43]. The quark-gluon plasma (QGP) forms at a later time in the collision and the early scattered partons move through the QGP region leading to the phenomenon known as *jet quenching* which is signified by a “depletion in the yield of high p_T hadrons” [43]. Observation of this jet quenching is therefore a “potential signature for QGP formation.”

The *nuclear modification factor* is a measure of nuclear effects and has been discussed by many authors [18,42–46]. For proton-nucleus reactions,

FIG. 7 (color online). π^- production in pp collisions. Data from reference [1] is plotted against the parameterization of Ellis [33]. Values of x_F and data and line multiplication are the same as Fig. 5.

$$R_{pA} = \frac{Ed^3\sigma_{pA}/d^3p}{N_{\text{coll}}Ed^3\sigma_{pp}/d^3p}. \quad (25)$$

For nucleus-nucleus reactions,

$$R_{AB} = \frac{Ed^3\sigma_{AB}/d^3p}{N_{\text{coll}}Ed^3\sigma_{NN}/d^3p}, \quad (26)$$

where NN refers to the nucleon-nucleon cross section. Instead of d^3p , other variables can be used such as x_F , p_T , rapidity, pseudorapidity, etc. The nuclear modification factor $R = 1$ in the absence of nuclear effects, i.e. if the nuclear cross section is just an incoherent superposition of nucleon-nucleon collisions. For low $p_T < 2$ GeV it has been found [43] that $R < 1$ and this is due to the fact that the reactions scales with the number of participants (participant scaling), rather than the number of binary collisions [43]. For $p_T > 2$ GeV “particle production in pA

FIG. 8 (color online). π^- production in pp collisions. Data from reference [1] is plotted against the parameterization of Mohov [34]. Values of x_F and data and line multiplication are the same as Fig. 5.

collisions is enhanced compared to binary scaling” [43], which is the Cronin effect.

Again consider *participant scaling versus binary scaling*. The nucleus-nucleus cross section could scale either as a function of the number of participants (often called wounded nucleons) or as a function of the number of binary nucleon-nucleon collisions. Binary scaling would indicate no collective effects whatsoever. However if there are some collective effects then these should manifest themselves by scaling with the number of participants. Obviously binary collisions are harder and lead to high p_T processes such as jet production (from individual parton collisions) and heavy flavor production. Participant effects are generally softer processes at smaller p_T such as soft hadron production, transverse energy flow and other collective phenomena. Both the number of participants N_{part} and the number of binary collisions N_{coll} is large for small impact parameter (central collisions) and drops off

FIG. 9 (color online). π^- production in pp collisions. Data from Ref. [1] is plotted against the parameterization of Carey [35]. Values of x_F and data and line multiplication are the same as Fig. 5.

smoothly at larger impact parameters (peripheral collisions). Also we always have $N_{\text{coll}} > N_{\text{part}}$, because there can be many rescatterings among the participants.

For a long time it has been known that energetic particle production in proton-nucleus collisions increases faster than the number of binary nucleon-nucleon collisions [46]. In other words, particle production in nuclear collisions is enhanced compared to binary scaling [43]. This is known as the *Cronin effect*. Various physical mechanisms can contribute to the Cronin effect such as multiple parton scattering in the initial stage of the collision [42], Fermi motion [44], etc. Reference [46] points out that “the cause of the Cronin effect and its species dependence are not yet completely understood,” where species dependence refers to the fact that the size of the effect varies for different particles produced. A contribution from final state interactions is also possible [46]. Reference [46] provides a very nice summary of the Cronin effect. The pA cross

FIG. 10 (color online). π^+ production in pC collisions. Data from Ref. [2] is plotted against the parameterization of Badhwar [10] multiplied by a best fit factor of $12^{0.9}$. The values of x_F from top to bottom are $-0.1, -0.075, -0.05, -0.04, -0.03, -0.025, -0.02, -0.01, 0.0, 0.01, 0.02, 0.025, 0.03, 0.04, 0.05, 0.06, 0.075, 0.1, 0.125, 0.15, 0.2, 0.25, 0.3, 0.4, 0.5$. Following Ref. [1], data and lines are multiplied successively by 0.5 to allow for a better separation.

section is parameterized as [46,47]

$$E \frac{d^3 \sigma}{d^3 p}(p_T, A) = E \frac{d^3 \sigma}{d^3 p}(p_T, 1) A^{\alpha(p_T)}, \quad (27)$$

where $\alpha > 1$ indicates nuclear collective effects. Adler *et al.* [46] state that “the enhancement depends on the momentum and the type of particle produced, with protons and antiprotons exhibiting a much larger enhancement than pions and kaons at $p_T > 2-3$ GeV.” They also point out that at $\sqrt{s} = 27.4$ GeV, the enhancement reaches a maximum at $p_T = 4.5$ GeV with $\alpha_K^+ \sim \alpha_\pi^+ = 1.1$ and that at the same momentum $\alpha_p = 1.3$ for protons [46].

In Figs. 10–13 we have simply multiplied the pp parameterizations of Badhwar and Mokhov by a constant Cronin enhancement factor, 12^α , and compared them to

FIG. 11 (color online). π^+ production in pC collisions. Data from reference [2] is plotted against the parameterization of Mokhov [34] multiplied by a best fit factor of $12^{0.9}$. Values of x_F and data and line multiplication are the same as Fig. 10.

the pC data from NA49 [2]. In our previous pp fits, the Badhwar parameterization worked best for high $p_T > 0.5$ GeV and the Mokhov parameterization worked best for low $p_T < 0.5$ GeV. Therefore we do not expect the Badhwar parameterization to fit low p_T data for the pC reaction and we do not expect the Mokhov parameterization to fit high p_T data for the pC reaction. We varied the value of α to find the best possible fit to the pC data. Figures 10 and 11 show the Badhwar fit to the high p_T data with a best value of $\alpha = 0.9$ and Figs. 12 and 13 show the Mokhov fit to the low p_T data also with an independent best value of $\alpha = 0.9$.

IV. CONCLUSIONS

The NA49 Collaboration [1,2] has provided new precise data on pion production in pp and pC reactions at a beam momentum of 158 GeV. Although a precise fit is not

FIG. 12 (color online). π^- production in pC collisions. Data from Ref. [2] is plotted against the parameterization of Badhwar [10] multiplied by a best fit factor of $12^{0.9}$. Values of x_F and data and line multiplication are the same as Fig. 10.

expected, nevertheless it is of interest to compare currently available arithmetic parameterizations to the new data. Let us emphasize that we are not suggesting that arithmetic parameterizations are able to give a complete account of the new data *et al.* [1,2]. The numerical interpolation developed by the NA49 Collaboration [1,2] is far superior. The aim of this paper has rather been to see how well some parameterizations describe the data.

We conclude that the Alper and Ellis parameterizations do not fit the pp data very well, and should not be used in this energy region. The Carey parameterization for π^- works better but underpredicts the data at low p_T for small values of x_F and the predictions at high p_T are only moderately good. The Badhwar parameterization for $\pi^\pm$ works well for high values of p_T , but does a poor job at low p_T , whereas the Mokhov parameterization is the other way around. It works best for low p_T but not well for high p_T . Note also that the Badhwar parameterization for π^- does not work well for large values of x_F , whereas the Mokhov

FIG. 13 (color online). π^- production in pC collisions. Data from reference [2] is plotted against the parameterization of Mokhov [34] multiplied by a best fit factor of $12^{0.9}$. Values of x_F and data and line multiplication are the same as Fig. 10.

parameterization works fine in this region. Regarding the pp parameterizations, we conclude that for low $p_T < 0.5$ GeV, it is best to use the Mokhov parameterization. For high $p_T > 0.5$ GeV, it is best to use the Badhwar parameterization, except for large values of $x_F > 0.45$, where it is better to use Mokhov.

Because the Badhwar and Mokhov parameterizations gave good fits in certain p_T ranges, we scaled them to the pC data. In the Cronin effect, the scaling factor is $A^{\alpha(p_T)}$, where A is the nucleon number. We found that the Badhwar parameterization gave the best fit for $\alpha \approx 0.9$, and the Mokhov parameterization also gave the best fit for $\alpha \approx 0.9$. As discussed above, the Badhwar parameterization works best for high p_T and the Mokhov parameterization works best for low p_T . Therefore we conclude that the Cronin enhancement factor for the pC reactions is $\alpha(p_T) \approx 0.9$ in both the high $p_T > 0.5$ GeV region and low $p_T < 0.5$ GeV region. These results indicate the absence of nuclear collective effects [46] for this pC reaction [2].
