Abstract

Background: Carboxysomes are polyhedral protein microcompartments found in many autotrophic bacteria; they encapsulate the CO₂ fixing enzyme, ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO) within a thin protein shell and provide an environment that enhances the catalytic capabilities of the enzyme. Two types of shell protein constituents are common to carboxysomes and related microcompartments of heterotrophic bacteria, and the genes for these proteins are found in a large variety of bacteria.

Methodology/Principal Findings: We have created a Halothiobacillus neapolitanus knockout mutant that does not produce the two paralogous CsoS4 proteins thought to occupy the vertices of the icosahedral carboxysomes and related microcompartments. Biochemical and ultrastructural analyses indicated that the mutant predominantly forms carboxysomes of normal appearance, in addition to some elongated microcompartments. Despite their normal shape, purified mutant carboxysomes are functionally impaired, although the activities of the encapsulated enzymes are not negatively affected.

Conclusions/Significance: In the absence of the CsoS4 proteins the carboxysome shell loses its limited permeability to CO₂ and is no longer able to provide the catalytic advantage RubisCO derives from microcompartmentalization. This study presents direct evidence that the diffusion barrier property of the carboxysome shell contributes significantly to the biological function of the carboxysome.

Introduction

Carboxysomes, primitive organelles found in many autotrophic bacteria, consist of a thin polyhedral protein shell that surrounds a core of ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO) holoenzyme molecules [reviewed in [1,2]]. RubisCO catalyzes the first step of the inorganic carbon (Ci) assimilation pathway, the Calvin-Benson-Bassham cycle. Sequestration of this rather inefficient enzyme into a protein microcompartment enhances RubisCO’s catalytic performance and permits the bacteria that form carboxysomes to grow at appreciable rates at ambient CO₂ concentrations. Mutants that are compromised in their ability to assemble functional carboxysomes have a high-CO₂-requiring (hcr) phenotype and do not grow at all or at greatly reduced rates, unless cultured in an atmosphere of elevated CO₂. The molecular mechanism by which carboxysomes enhance the catalytic performance of RubisCO is in part attributable to the carbonic anhydrase activity of the shell-associated CsoSCA protein. This enzyme catalyzes the dehydration of cytosolic bicarbonate to CO₂, the only Ci species RubisCO can use. In addition, the carboxysome shell constitutes a diffusional barrier for CO₂, thereby preventing leakage of this Ci species out of the microcompartment and allowing the carboxysome to function as a CO₂ trap that provides RubisCO in the interior with an on-demand supply of its substrate, CO₂ [3].

Carboxysome-like polyhedral inclusions are not limited to autotrophic bacteria (reviewed in [4]). Microcompartments of similar appearance have also been observed in gram-negative and gram-positive heterotrophs during growth on certain carbon sources. Instead of RubisCO, these structures encapsulate enzymes that participate in the catabolism of the organic carbon species that induces microcompartment formation. The potential to form protein organelles is widespread among the bacteria [5], suggesting that microcompartmentalization of key metabolic steps constitutes a general regulatory strategy in prokaryotes.

All bacteria that have the potential to form carboxysome-like inclusions share two sets of genes that are thought to encode shell components common to all polyhedral protein microcompartment...
ments [2]. The genes for bacterial microcompartment domain (BMC; pfam 00936) proteins are always present in multiple paralogs that encode highly abundant shell components. Representatives of α- and β-carboxysomes are the CsoS1 and CcmK/CcmO proteins, respectively. These proteins readily form homo-hexamers that, in turn, assemble into two-dimensional sheets in crystals [5,6]. The BMC proteins are believed to form the facets of the icosahedral carboxysomes and related microcompartments [5,6,7,9,10,11].

The other protein family (pfam 03319) common to all polyhedral protein microcompartments is represented by the two paralogs csoS4A and csoS4B (formerly ofC and ofB, respectively) in the α-carboxysome operon, and by the ccmL gene in β-carboxysome gene clusters [12]. Recombinant CsoS4A from H. neapolitanus and CcmL from Synechocystis 6803 crystallize as hexamers and therefore begs the question whether another of the Eut proteins forms pentamers. To examine more closely the role of the pentamer-forming shell components, CsoS4A and CsoS4B, in the well-characterized α-carboxysome of Halothiobacillus neapolitanus, a deletion mutant was created that is deficient in both paralogs. We have characterized the mutant with respect to growth phenotype and to carboxysome composition and function. Here we show that the CsoS4 proteins are apparently not essential determinants of carboxysome shape but are vital for the diffusion barrier properties of the shell.

**Results**

**Wild type α-carboxysomes contain CsoS4A and CsoS4B polypeptides**

Previous work had established that all genes of the cso operon, including csoS4A and csoS4B, are transcribed in H. neapolitanus. Furthermore, in cells grown in ambient CO2 the steady-state transcript levels for those proteins that can be resolved by one-dimensional SDS-PAGE correlate with their abundance in the carboxysome [17]. These results suggested that all proteins encoded by the cso operon are present in α-carboxysomes. However, the low-abundance CsoS4 proteins were never reliably shown to be present in purified carboxysome preparations. Another factor that complicates the detection of these two putative carboxysome proteins is the inability to separate the paralogs CsoS1A and CsoS1C by conventional one-dimensional gel electrophoresis [1]. These two CsoS1 proteins have almost identical amino acid sequences and migrate as a single band that would probably also include the slightly smaller CsoS4A and CsoS4B polypeptides. To probe the presence of the low-abundance CsoS4 proteins, both polypeptides were overexpressed as histidine-tagged recombinant proteins in E. coli [10] and used to generate polyclonal antisera. As expected from the considerable similarity in primary sequence of both proteins [12], the antibodies raised against each CsoS4 protein cross-reacted equally well with the other paralog (not shown).

To separate the CsoS4A and CsoS4B polypeptides based on differences in their predicted isoelectric points and distinguish them from the bands of the highly abundant CsoS1 proteins, a shell-enriched carboxysome fraction was subjected to one-dimensional SDS-PAGE. To separate the CsoS4A and CsoS4B polypeptides based on differences in their predicted isoelectric points and distinguish them from the bands of the highly abundant CsoS1 proteins, a shell-enriched carboxysome fraction was subjected to two-dimensional gel electrophoresis. The pattern of stained polypeptide spots on the resulting gel was rather complex (Figure 1A) and

The HncsoS4AB::Km double knockout mutant displayed a strict hcr phenotype (Figure 3), showing no signs of growth for over 70 h in an ambient CO2 atmosphere. In air supplemented with 5% CO2, on the other hand, the mutant culture grew at a rate similar to that of the wild type but did not reach the stationary phase cell density as the wild type. This phenotype suggested that deletion of both csoS4 genes may have prevented the assembly of carboxysomes or that the function of mutant carboxysomes was severely impaired.

The HncsoS4AB::Km mutant forms carboxysomes

Sectioned cells were examined by TEM to determine if the double knockout mutant produced carboxysomes. As seen in Figure 4A–D, many cells contained greatly elongated carboxysomes that were reminiscent of the malformed β-carboxysomes seen in the S. elongatus PCC7942 ccmL insertion mutant [13,14]. Notably, several cells that were in the process of dividing contained very long mutant carboxysomes that extended across the constriction site between pairs of daughter cells and seemed to prevent complete fission (Figure 4C and D). The apparent interference of elongated carboxysomes with cell division could explain the inability of the HncsoS4AB::Km mutant culture to reach wild-type cell densities but hardly accounted for the absolute hcr phenotype (Figure 3).

The observation that individual mutant cells contained carboxysomes of apparently normal appearance in addition to malformed one (Figure 4A–D) was most surprising in light of the purported role of the CsoS4 proteins in the carboxysome [10]. In fact, “normal” carboxysomes seemed to outnumber elongated ones in cell thin sections. To obtain a more quantitative picture of the ratio of icosahedral to elongated carboxysomes in the mutant and in the wild type, carboxysomes were counted in a large number of cell thin sections in random fields of vision, regardless of the orientation in which cells and inclusions were cut (Table 1). In thin sections of wild type cells an average 0.38 carboxysome was visible per cell; no abnormally shaped microcompartments were observed in the 340 cells that were counted. Within the 376 mutant cell sections that were examined, 141 carboxysomes were observed, which translates to an average 0.38 carboxysome per mutant cell (approximately 2/3 of wild type). Less than 13% (18) of the mutant carboxysomes appeared to be elongated, suggesting that in HncsoS4AB::Km cells “normal” carboxysomes were an order of magnitude more prevalent than abnormally shaped ones.

Purified “normal” HncsoS4AB::Km carboxysomes outnumber elongated ones

Cells from a chemostat culture of the HncsoS4AB::Km mutant were subjected to a standard carboxysome isolation procedure [3,15,18] because of concerns that the orientation in which the
embedded mutant cells were sectioned might have influenced the apparent shape of the carboxysomes in cell thin sections and could have led to an over-estimation of “normal” carboxysomes. Following enrichment by differential centrifugation, carboxysomes were recovered from a band in the sucrose gradient that had formed at approximately the same position as one composed of wild type organelles. Transmission electron microscopy revealed that the majority of these carboxysomes were of normal appearance (Figure 5). Of 312 negatively stained carboxysomes counted in 20 randomly selected fields of vision, less than 2% had an abnormal shape; a comparable number of purified wild type carboxysomes contained no misshapen ones (Table 1).

Mutant carboxysomes are devoid of CsoS4A and CsoS4B

Despite their low abundance in the carboxysome, the CsoS4 proteins could easily be visualized on an immunoblot of wild type cell extract probed with anti-CsoS4B antibody (Figure 6A, lane 3). By contrast, no CsoS4 protein was detectable in an equivalent amount of HncsoS4AB::Km mutant extract (Figure 6A, lane 4), indicating that the mutant cells, as expected, produced neither CsoS4A nor CsoS4B. The same result was obtained with immunoblots of purified carboxysomes (Figure 6B, lanes 3 and 4). As judged by the pattern of stained polypeptides on an SDS-polyacrylamide gel, the protein composition of mutant carboxysomes was essentially indistinguishable from that of their wild type counterparts (Fig. 6B, lanes 1 and 2). The immunoblot signals for the major shell components, the CsoS1 paralogs, were comparable in mutant and wild type particles (Figure 6B, lanes 6 and 7). These results suggested that mutant carboxysomes of normal shape could be formed in the absence of both CsoS4 paralogs.

The shell of mutant carboxysomes is leaky

To determine whether a reduced carboxysomal CO2 fixation activity could explain the strict hcr phenotype of the HncsoS4AB::Km

![Figure 4. Transmission electron micrographs of HncsoS4AB::Km cells. mutant, radiometric Rubisco activity assays were performed with sucrose gradient-purified mutant and wild type carboxysomes as described [3] (Table 2). Results from triplicate assays performed with two independent carboxysome preparations established that the V_max values for mutant carboxysomes (1.6±0.1 μmol-min⁻¹·mg⁻¹) were very close, if not identical, to those of wild type particles (1.8±0.1 μmol-min⁻¹·mg⁻¹). Surprisingly, the K_C for mutant carboxysomes (124±5.7 μM CO₂) was lower by approximately 24% than that measured for their wild type counterparts (163.3±8.4 μM CO₂). Since “normal” carboxysomes represented the majority of microcompartments purified from the mutant by a wide margin, these results suggested that, despite their apparently icosahedral shape and close-to-wild type protein composition, mutant carboxysomes lacking CsoS4A and CsoS4B were more permeable to Ci than wild type particles.

Since in wild type carboxysomes the activity of the shell-associated carbonic anhydrase, CsoSCA, and the limited permeability of the shell for inorganic carbon are crucial for the catalytic enhancement Rubisco derives from being compartmentalized [3], we measured the carbonic anhydrase activity of purified mutant and wild type carboxysomes with stopped-flow changing indicator assays [19] as described previously [20]. Clearly, the CsoSCA-catalyzed rate of bicarbonate dehydration was two to three fold faster in mutant carboxysomes than in wild type particles, as seen by the steeper slope of the pH change plots (Figure 7). The same difference in catalytic rates was also observed for the CO₂ hydration reaction (not shown). Since the observed rate enhancement could not be explained by a significantly higher abundance of the carbonic anhydrase in mutant carboxysomes, this result also suggested that the shell of carboxysomes deficient in CsoS4A and CsoS4B is more permeable to inorganic carbon species.

Discussion

Genes that are homologous to the carboxysomal csoS4/ccmL and csoS1/ccmK paralogs are found in the genomes of many bacteria [5], indicating that the genetic potential to compartmentalize key metabolic reactions in protein compartments is widespread among prokaryotes. The co-occurrence of the two types of genes that encode proteins believed to form facets (CsoS1/CcmK) and vertices (CsoS4/CcmL) of the icosahedral carboxysomes [10] further suggests that the polyhedral shells of all bacterial microcompartments share a common building principle, despite variations in shell protein structures [5,6,7,8,9,10,11], compositions and microcompartment functions [2,4]. These two classes of shell proteins are clearly important for microcompartment structure and/or function.

CsoS4A and CsoS4B, the two smallest proteins encoded by the cso operon of H. neapolitanus, were shown to be present in
α-carboxysomes in approximately equimolar, yet extremely low amounts. Their low abundance was expected based on the proposed function of CsoS4A pentamers at the carboxysome vertices and on their low steady state transcript levels [10,17]. Likewise, the elongated carboxysomes that were apparent in thin sections of the HncsoS4AB::Km double knockout mutant were not surprising, since a similar phenotype had been observed in a S. elongatus mutant [13,14,21]. Interestingly, misshapen carboxysomes have occasionally also been observed in wild type cells of H. neapolitanus and other thiobacilli [22,23] (Iancu et al., submitted), as well as in S. elongatus PCC7942 [24], where they are, however, rare compared to their abundance in the H. neapolitanus csoS4AB:Km double knockout and in the S. elongatus ccmL mutant. The existence of the occasional malformed carboxysome in wild

**Figure 6. The HncsoS4AB::Km mutant does not produce CsoS4 protein.** (A) Crude cell extract (50 µg) and (B) purified carboxysome (10 µg) proteins were separated by SDS-PAGE (lanes 1, 2). Blots were probed with anti-CsoS4B (lanes 3–5) and anti-CsoS1B (lanes 6, 7) antiserum. Wild type: lanes 1, 3, 6; mutant: lanes 2, 4, 7; lane 5: 10 ng rCsoS4 protein (1:1 mixture of CsoS4A and CsoS4B). The reduced migration rate of the recombinant CsoS4 proteins is due to their C-terminal hexa-histidine tag. The mutant does not produce CsoS4A and CsoS4B.
doi:10.1371/journal.pone.0007521.g006

**Figure 7. Catalytic activity of the carboxysomal carbonic anhydrase CsoSCA.** The increase in pH upon dehydration of bicarbonate to CO$_2$ by CsoSCA was followed using a colorimetric stopped-flow assay [19]. In the representative plot shown, the open circle trace shows the apparently faster kinetics (steeper initial slope) of CsoSCA activity in HncsoS4AB::Km mutant carboxysomes; the filled circle trace indicates wild type.
doi:10.1371/journal.pone.0007521.g007
type bacteria and the increased number of elongated carboxy-
osomes in mutants deficient in the CsoS4/CcmL proteins suggested
that the outcome of the carboxysome shell assembly process in vivo
depends on the balanced availability of all structural components.
Ectopic expression of the PduA protein in a Salmonella enterica pduA
deletion mutant under conditions in which formation of the
propanediol utilization (Pdu) microcompartment was induced resulted
in a mixture of normal and abnormal microcompartments
[25]. Likewise, when individual Pdu proteins were overexpressed
resulted in a mixture of normal and abnormal microcompartments
in E. coli in addition to the entire pdu operon from Citrobacter
freundii, inclusions of abnormal size and/or shape, indicative of
non-physiological protein assemblies, were observed [26].

The coexistence of “normal” and elongated carboxysomes in
mutant cells and among the population of purified mutant
carboxysomes was unexpected and indicated that, contrary to
the prediction of the current shell model [10], the two CsoS4
proteins are not essential shape determinants in the shell of
α-carboxysomes. However, it is possible that subtle variations in shell
structure and deviations from an icosahedral shape remained
undetected in the transmission electron micrographs of negatively
stained carboxysomes. To obtain a more comprehensive and
physiologically relevant picture of the range of shapes exhibited by
carboxysomes that lack the CsoS4 paralogs, a thorough cryo-
electron tomography study would be required. This technique
yields images of cells and organelles in their near-in vivo state and
eliminates many of the artifacts that are often associated with the
preparation of biological material for standard TEM.

The predominance of “normal” carboxysomes in the Hncso-
S4AB::Km mutant implicated other carboxysome shell compo-
ment(s) as potential vertex proteins. The three CsoS1 paralogs
come to mind since they are the major shell components of α-
carboxysomes. However, since CsoS1A [6], and its homologs
[5,6,7,8,10,11] form crystals of hexamers or pseudo-hexamers, one
would have to postulate that a BMC domain (pfam00936) protein
is able to form pentamers as an alternative quaternary structure in
the absence of both CsoS4 proteins. Precedents for multiple
oligomeric states of proteins are found among those icosahedral
viruses whose capsids are built from a single protein species
(reviewed in [27]). Likewise, a presumed shell protein of β-
carboxysomes, the CsoS1 ortholog CcmK2, also appears to
assume quasi-equivalent oligomeric structures in vitro [5]. In light
of this finding it is possible that one of the three CsoS1 paralogs
of α-carboxysomes also possesses structural flexibility and fulfills
the role of the missing CsoS4 proteins in the double knockout mutant
HncsoS4AB::Km. It is noteworthy that the EutN protein crystallizes
as hexamers [10]. Since this protein is the sole CsoS4 homolog in the
Salmonella enterica eut operon, which encodes the ethanolamine
utilization (Eut) microcompartment [28], pentameric assemblies
would have been expected based on the similarity of its primary
sequence to the CsoS4/CcmL proteins. Presumably, in the Eut
microcompartment one of the other shell proteins, all of them
CsoS1 homologs, may form pentamers.

The apparent structural flexibility of the two shell components
common to bacterial microcompartments probably explains the
considerable variability in size and shape of the organelles. While
the exact composition of most microcompartments, including that
of β-carboxysomes, is not known, the α-carboxysomes of H. neapolitanus
are able to tolerate considerable deviations from their
wild type protein composition without major effects on gross shell
shape. For example, carboxysomes lacking the shell-associated
carbonic anhydrase CsoSCA also appear to be of normal
icosahedral shape and protein composition (sans CsoSCA) [3].
While the argument can be made that this lack of a detrimental
effect on shell shape is easily explained by the low abundance of
CsoSCA in the carboxysome [1,29], Menon et al. clearly showed
that the biogenesis of carboxysome shells does not require the
presence of the highly abundant microcompartment cargo,
RubisCO, and that carboxysomes can encapsulate chimeric and
foreign RubisCO species [10].

The carboxysomes of the double knockout mutant Hncso-
S4AB::Km, despite their apparently normal shape, were clearly
functionally impaired, as indicated by the absolute requirement
of the mutant for elevated CO2. It was difficult to reconcile the strict
hcr phenotype with the relatively small number of malformed
carboxysomes present, particularly since a CsoSCA deletion
mutant and several RubisCO replacement mutants [3,18] are
able to grow in air, albeit more slowly than the wild type. Clearly,
the highly elongated mutant carboxysomes interfered with cell
fission. However, since carboxysomes of apparently normal shape
greatly outnumbered malformed organelles and not all cells
contained elongated carboxysomes, this impairment alone should
not result in an absolute hcr phenotype. A closer look at purified
elongated carboxysomes revealed that, like carboxysomes of a
RubisCO replacement mutant described previously [18], these
microcompartments appeared to contain aggregated holoenzyme
complexes (Figure 5B and C) of potentially compromised CO2
fixation ability; these may have contributed to, but do not explain
entirely, the strict hcr phenotype of the mutant.

The lower value for KC in mutant than in wild type
carboxysomes was surprising in view of the normal appearance
of the large majority of mutant carboxysomes and the low
abundance of the CsoS4 proteins in wild type organelles. The
value of KC in the mutant was strikingly similar to that measured
for broken wild type carboxysomes [3] and suggested that the
permeability barrier function of the carboxysome shell for Ci is
compromised in HncsoS4AB::Km organelles. Indeed, the apparently
higher activity of the shell-associated carbonic anhydrase CsoSCA,
which faces the inside of the carboxysome [3], suggested that this
enzyme has more ready access to its substrate (CO2 or HCO3−) in
mutant than in wild type carboxysomes. Shell “leakiness” for the
RubisCO substrate CO2 is thereby implicated as the major factor
leading to the strict hcr phenotype of the HncsoS4AB::Km mutant.
Price et al. [13] measured the dissipation of the intracellular Ci pool
following transfer of S. elongatus PCC4972 from light to dark and
found that Ci was lost from the ccmL deletion mutant P Val at a
considerably higher rate than from the wild type. The authors
offered as two explanations for their observation: 1) the possibility
of accelerated CO2 leakage from the mutant carboxysomes, and 2)
the lower specific activity of the carboxysome-associated carbonic
anhydrase. Our results support the first scenario. Apparently,
carboxysomes lacking the shell proteins CsoS4A and CsoS4B,
despite being able to assume an apparently normal shape and
displaying near wild-type protein composition (sans CsoS4A
and CsoS4B), lack the protein interactions that are necessary to form
a “CO2-tight” shell. The mutant organelles therefore cannot
provide the catalytic advantage RubisCO derives from being
sequestered into wild type carboxysomes. The shell proteins
CsoS4A and CsoS4B, although of very low abundance, clearly
fulfill an important structural role in the shell and are vital to
carboxysome function in the carbon dioxide concentrating
mechanism (CCM) of H. neapolitanus.

Materials and Methods

Bacterial strains and growth
Halothiobacillus neapolitanus c2 (ATCC23641) and the Hncso-
S4AB::Km mutant of this strain were grown at 30°C in a 2 L
chemostat as described previously [3]. To establish a growth
curve, 50 ml batch cultures of wild type and mutant were maintained in air and in air supplemented with 5% CO₂. Growth was monitored by measuring the OD₆₀₀ with a Beckman Coulter DU 800 spectrophotometer.

Genomic DNA isolation
A 50 ml batch culture was grown to saturation and harvested by centrifugation at 9,000 rpm for 15 min at 4°C (Beckman JA 25.5 rotor). A Zymo Fungal/Bacterial DNA Kit (Zymo Research, Orange, CA) was used to purify genomic DNA, following the manufacturer’s protocol with one modification: an additional 1 min spin at 10,000 rpm in a fresh 1.5 ml tube was performed immediately before elution of the DNA from the column.

Recombinant CsoS4 protein expression and antiserum generation
The csoS4A (GenBank AAC32553.1) and csoS4B (GenBank AAC32554.1) expression clones in the pET-22b (+) vector (Novagen/EMD, Gibbstown, NJ) were generated by first amplifying the csoS4A and csoS4B coding sequences from pTn1 [30] using PhiUltra II DNA polymerase (Stratagene, La Jolla, CA) with primer pairs oAmEc1/oArXhoIns and oBrNcoI/oBrXhoIns, respectively (Table S1). The primers contain restriction sites for in-frame ligation into the multi-cloning site of the vector. The resulting recombinant plasmids were transferred into chemically competent E. coli BL21(DE3) cells. Induction of protein expression and purification of the recombinant protein were as previously described [10]. Polyclonal antibodies were raised against both his-tagged CsoS4 proteins (Cocalico Biologicals, Reamstown, PA).

Generation of the HncsoS4AB::Km double deletion mutant
The HncsoS4AB::Km deletion mutant was generated by replacing the csoS4A and csoS4B genes with a kanamycin resistance cassette in the H. neapolitanus genome. The kanamycin resistance cassette was PCR-amplified from the pCR-BluntII-TOPO vector (Invitrogen) with primers oAKmF and oBKmR (Table S1). The PCR product was electroporated into E. coli DY330 cells [31] containing the pTN4.3 plasmid. This plasmid consists of a 4.3 kb EcoRI fragment of the H. neapolitanus cso operon (AF038430.1) that encompasses the region between the 3'-half of csoS2 and the 3'-end of csoS1B in the vector pT7/T3x18 (J.M. Shively, unpublished). The csoS4A-csoS4B coding sequences in pTnE4.3 were replaced with the kanamycin resistance cassette via homologous recombination, yielding plasmid pTnE4.3-oAKmKm. This plasmid was introduced into exponentially growing H. neapolitanus cells by electroporation [32] to generate the HncsoS4AB::Km mutant by homologous recombination. Transformants were selected by growth on kanamycin-containing medium in a 5% CO₂-enriched atmosphere. The mutant genotype was confirmed by diagnostic PCR amplification of genomic DNA with primer pairs S355368/1Cr6735 and orfA6211/orfBr6472 (Table S1) and by sequence analysis (University of Maine DNA Sequencing Facility).

Carboxysome purification and protein analyses
Carboxysome isolation and shell enrichment procedures were as previously described [3,13,15]. Proteins were separated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) in precast 10–20% gradient gels (Bio-Rad) and stained with Gelcode Blue (Thermo Scientific/Pierce). For two-dimensional electrophoresis, 88 μg of a carboxysome shell-enriched fraction were applied to an 11 cm, pH 4–7 ReadyStrip IPG strip (Bio-Rad). The strip was rehydrated and loaded with protein overnight at 20°C. Isoelectric focusing proceeded at 20°C and 50 μA per strip at a rapid ramping rate to a maximum voltage of 8,000 V (total 40,000 V-h). Electrophoresis in the second dimension was as described for one-dimensional SDS-PAGE.

To detect the CsoS4B protein(s) in cell extracts and purified carboxysomes, gel blots were probed with rabbit polyclonal anti-CsoS4B antiserum as primary antibody and goat anti-rabbit horseradish peroxidase-conjugated IgG as secondary antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA). Blots were developed using SuperSignal West Pico chemiluminescent substrate (Thermo Scientific/Pierce) prior to visualizing immunoreactive bands with a VersaDoc imaging system (model 4000 MP; Bio-Rad).

Concentrations of purified proteins were determined with the BCA assay (Thermo Scientific/Pierce, Rockford, IL). Protein concentrations of cultured cells were estimated with a modified Lowry assay (Thermo Scientific/Pierce). Bovine serum albumin served as standard in both assays.

Enzyme assays
Rubisco activity assays for the determination of K₅; and Vₐₘₙ values of wild type and mutant carboxysomes were performed in triplicates with two independent carboxysome preparations as described previously [3].

To quantify the carbonic anhydrase activity of purified carboxysomes, colorimetric stopped-flow changing indicator assays [19] were performed to measure CO₂ hydration and HCO₃⁻ dehydration as described previously [3].

Transmission electron microscopy
Exponentially growing wild type and mutant H. neapolitanus cells were gently centrifuged and the cell pellet resuspended in molten agarose (0.8% w/v in sterile water) at approximately 40°C. Bacteria in the solidified agarose plug were fixed for 2 h in 2.5% glutaraldehyde buffered in 0.1 M sodium cacodylate, pH 7.0. Cells were rinsed with 0.1 M sodium cacodylate, pH 7.0, and postfixed for 45 min in cacodylate-buffered 1% osmium tetroxide (pH 7.0). Cells were rinsed in distilled water, dehydrated in ethanol ranging from 50% to 100% followed by acetone, infiltrated in ERL 4206 resin (Spurr’s), and cured at 70°C for 36 hours. Spurr’s resin contained nonenyl succinic anhydride (26 g), vinyl cyclohexene dioxide (10 g), diglycidyl ether (6 g), and dimethylaminomethanol (0.2 g). Ultrathin sections were taken using a Porter-Blume MT-2B ultramicrotome with a diamond knife and collected on 200 mesh copper grids. Grids were stained in a moist chamber on drops of lead citrate [33] for 15 min, followed by 2% aqueous uranyl acetate for 15 min. Purified carboxysomes were negatively stained as previously described [3]. Specimen were viewed using a Zeiss 109T transmission electron microscope.

Supporting Information
Table S1 PCR primers used in this study.
