ABSTRACT

DOES THE USE OF A REGIONAL NERVE BLOCK DECREASE THE INCIDENCE OF POST OPERATIVE NAUSEA AND VOMITING, DECREASE PAIN SCORES, OR DECREASE DISCHARGE TIME COMPARED TO GENERAL ANESTHESIA ALONE?

by Donald Lane Whitney

December 2015

Problem Statement: The use of regional anesthesia in orthopedic surgeries has been shown to decrease the rate of postoperative nausea and vomiting (PONV), postoperative pain, and decrease postoperative discharge time. However, some healthcare facilities continue to provide anesthesia for these procedures without the use of regional anesthesia techniques.

Purpose: The purpose of this capstone project was to determine if the addition of a regional anesthetic technique would be beneficial to the patient and cost efficient to the healthcare facility.

Methods: A retrospective chart review was conducted and data collected on the population of interest. Inclusion criteria were patients undergoing orthopedic surgery of the upper extremity during January 2015 through August 2015, ages 35-65, and patient status classification I, II, or III. A total of 24 charts were reviewed with 12 charts in the general anesthesia group and 12 charts in the regional anesthesia group. PONV, postoperative pain, anesthesia time, and length of stay in the post anesthesia care unit (PACU) were compared between the groups.
Analysis: Unpaired t-tests were used to compare the anesthesia time, PACU length of stay, antiemetic medication requirements, and opioid medication dosage between the two groups. There were no significant differences found between the groups.

Conclusion: This retrospective chart review found no significant differences between the groups related to antiemetic medications, opioid medication dosages, or length of stay in PACU.
ACKNOWLEDGMENTS

Special thanks to my committee members, Dr. Kathleen Masters, committee chair and committee members Dr. Vickie Stuart and Dr. Michong Rayborn for their support and guidance.

I would also like to thank Dr. Joe Campbell, Medical Director of anesthesia at Forrest General Hospital and Dr. Edmund Bagingito, Medical Director of anesthesia at The Orthopedic Institute for their support.

CHAPTER I
INTRODUCTION

Several different types of anesthetic plans are possible for specific orthopedic surgical procedures. The use of regional anesthesia, combined regional anesthesia and general anesthesia, or general anesthesia as the sole anesthetic are different types of anesthetic plans used for orthopedic surgeries. The choice of the anesthetic technique, whether incorporating regional anesthesia or general anesthesia alone, is dependent upon the provider administering the anesthetic, the comorbidities of the patient, and the common practice of the facility.

Facilities throughout this region are no different, some use general anesthesia only while some use a combination of regional and general. An example to highlight this point is that two facilities in which nurse anesthesia students rotate in the local area have vastly different anesthesia techniques for orthopedic procedures of the upper extremity. One facility utilizes peripheral nerve blockade in nearly 100% of the orthopedic procedures. Another facility rarely utilizes peripheral nerve blockade for orthopedic surgical procedures.

Research has demonstrated some of the advantages of regional anesthesia over using general anesthesia alone. Egol et al. (2012) found that patients who had regional anesthesia compared to general anesthesia and were undergoing surgery for distal radius fracture had a decrease in pain perception at 3 and 6 months, an increase in wrist and finger motion at 3, 6, and 12 months, and an increase in functional scores at 3 months follow up. The findings of this
study are similar to results of other research related to postoperative pain control and postoperative nausea and vomiting. In patients receiving outpatient knee arthroscopy, Hadzic et al. (2005a) found a PONV rate of 12% in those receiving regional anesthesia versus 62% in those receiving general anesthesia. From the mentioned research studies available, it is clear that regional anesthesia offers a superior profile in regards to PONV and postoperative pain control.

The Neuman systems model correlates well with this capstone project. The concepts within the Neuman systems model are human beings, environment, health, and nursing (Whetsell, Gonzalez, & Moreno-Fergusson, 2015). Since this model is a systems model, the concepts are interrelated within the system as a whole. Neuman suggested that variables of the person should also be considered which include physiological, psychological, sociocultural, developmental, and spiritual (Whetsell et al., 2015). Considering the variables within the Neuman systems model, the physiological aspect may be improved with regional anesthesia because of increased rehabilitation after the operation and a decrease in pain scores. The psychological, sociocultural, developmental, and spiritual components may be improved because of a faster return to baseline function.
CHAPTER II
REVIEW OF LITERATURE

Regional anesthesia techniques offer multiple advantages to patients and healthcare facilities. Patients benefit from a reduction in postoperative pain and PONV. Facilities benefit from the inclusion of regional anesthesia techniques by increasing economic benefits to the facility and the patient, decreasing PACU length of stay, and increasing patient satisfaction ratings.

Postoperative Nausea and Vomiting

Chan et al. (2001) compared patients receiving general anesthesia, patients receiving an axillary nerve block, and patients receiving intravenous bier block and found the PONV rate to be 62%, 12%, and 18% respectively. In patients receiving outpatient knee arthroscopy, Hadzic et al. (2005a) found a PONV rate of 12% in those receiving regional anesthesia versus 62% in those receiving general anesthesia. Yauger et al. (2010) performed a retrospective chart review comparing patients receiving general anesthesia to regional anesthesia for knee or shoulder arthroscopy and found the antiemetic dose to be 0.58 for the general anesthesia group compared to 0.04 for the regional anesthesia group. Lane, Blundell, Mills, and Charalambous, (2014) found that the PONV mean score was 2.4 rated on a 0-10 scale.

Postoperative Pain

Chan et al. (2001) compared patients receiving general anesthesia to patients having an axillary nerve block for hand surgery and found that 85% of patients receiving general anesthesia complained of pain in PACU compared to
43% of patients receiving an axillary nerve block. Hadzic et al. (2005a) found that 16% of patients receiving a peripheral nerve block for knee arthroscopy required pain medications in PACU compared to 32% of patients receiving general anesthesia for the same procedure. Yauger et al. (2010) found that patients receiving regional anesthesia for knee and shoulder arthroscopy received 15.1 mg of morphine equivalency dosing compared to 22.9 mg for patients receiving general anesthesia. Tandoc, Fan, Kolesnikov, Kruglov, & Nader (2011) found the administration of postoperative pain medication was significantly lower in patients receiving regional anesthesia compared to patients receiving general anesthesia. Lee et al. (2012) found that patient controlled analgesia (PCA) with suprascapular nerve block yielded better postoperative pain scores than PCA alone. Egol et al. (2012) found that patients who had regional anesthesia compared to general anesthesia and were undergoing surgery for distal radius fracture had a decrease in pain perception at 3 and 6 months, an increase in wrist and finger motion at 3, 6, and 12 months, and an increase in functional scores at 3 months. Lane et al. (2014) found that patients receiving a nerve block had a mean pain score of only 3.5 in the postoperative phase of care.

Although there is an overwhelming amount of research in support of peripheral nerve blocks for postoperative pain improvement, some research suggests that peripheral nerve blocks using a local anesthetic in conjunction with other medications will prolong the block by a significant margin. An example of this is research conducted by Conroy and Awad (2011) who found that
interscalene blocks to be effective from a median of 13.8 hours for local anesthetic only to a median of 24.3 hours by adding dexamethasone to the local anesthetic. Conroy and Awad, (2011), compared local anesthetic only to local anesthetic with dexamethasone 4 mg and dexamethasone 8 mg but found no significant difference between the low dose group and high dose group.

Economic Implications

Schuster, Gottschalk, Berger, and Standl (2005) found regional anesthesia to be more expensive to perform and had economic benefits only if the procedure was longer than 200 minutes. However, Chan et al. (2001) found that intravenous regional anesthesia was the cheapest anesthetic while peripheral regional anesthesia to be the most expensive but was not significantly different from general anesthesia. Since patient satisfaction may have implications for reimbursement rates, an increase in patient satisfaction should be viewed as an economic benefit. Lane et al. (2014) found that 88% of patients receiving regional anesthesia responded satisfied, very satisfied, or extremely satisfied.

There has been research completed that supports the belief that regional anesthesia is more time consuming upon initiation but has faster discharge times while general anesthesia has faster initiation times but slower discharge time. Yauger et al. (2010) studied patients in the same day surgery unit and found that regional anesthesia had a longer preparation time and shorter discharge time when compared to general anesthesia, but the overall length of stay was nearly identical for the two groups. A similar study conducted by Hadzic et al. (2005a)
found that patients who received an interscalene block for rotator cuff surgery were ready for discharge 2.5 hours sooner than patients receiving general anesthesia for the same operation. Pavlin et al. (1998) researched factors affecting discharge time in outpatient procedures and found that patient receiving general anesthesia had discharge times 2.5 times longer than patients who had received regional anesthesia. Although the initial cost to implement a regional nerve block is higher due to the higher salary of the anesthesia provider, this cost may be offset by a shorter length of stay during the postoperative period.

The use of ultrasound guided regional anesthesia shows promise in regards to increasing the rate of successful peripheral nerve blocks. Liu, Ngeow, and YaDeau (2009) found that ultrasound reduced block performance time, achieved adequate nerve block in fewer attempts, and nerve block had a faster onset time. McCartney, Lin, and Shastri (2010) also found that ultrasound guided nerve blocks yielded faster block time, faster block onset, and a lower failed block rate. A research review by Neal et al. (2010) found similar results in regards to ultrasound guided blocks resulting in faster onset time and a higher success rate, but also found a reduced amount of local anesthetic to achieve an adequate nerve block. The reduction of local anesthetic volume research was replicated by Koscielniak-Nielsen and Dahl (2012).

There are other factors to consider when comparing regional anesthesia to general anesthesia. One factor to consider is unplanned admission rates. In patients who were undergoing rotator cuff repair, Hadzic et al. (2005b) found a
16% rate of unplanned admissions after general anesthesia compared to 0% in the group receiving regional anesthesia.

There is a large amount of evidence in support of regional anesthesia techniques when applied in the anesthetic plan. Marhofer, Willschke, and Kettner (2010) reported that regional anesthesia would continue as an economic benefit to facilities and patients as long as efficiency and success is directed toward anesthesia workflow. The trend in the use of regional anesthesia techniques will likely continue and expand with improvements in ultrasound technology.
CHAPTER III

METHODOLOGY

After Institutional Review Board approval, a retrospective chart review was conducted to collect data on the population of interest. The chart reviews were conducted at a level II trauma center and an orthopedic specialty center, both located in the southeastern region of the United States. Inclusion criteria were patients undergoing orthopedic surgery of the upper extremity, ages 35-65, and met patient status classification I, II, or III. The first group was composed of patients who received an interscalene block, supraclavicular block, or axillary block for postoperative pain control. The peripheral nerve blocks of interest were accomplished by ultrasound guidance as well as the use of a nerve stimulator needle. The ultrasound is used to identify anatomy, decrease the occurrence of vascular insult, and to assess the adequacy of local anesthetic spread. The stimulator needle is used to accomplish fine adjustments in needle placement by obtaining the desired muscle group motor twitches. The local anesthetic used in the peripheral nerve blocks of interest is 20-30 milliliters of Ropivacaine 0.5%. The second group included patients who received general anesthesia only. Exclusion criteria from this chart review included multisystem trauma patients. The reason for this patient population being excluded was because of skewed data related to pain medication due to trauma related comorbidities. Patients who received a continuous nerve block by catheter were also excluded.

The patient status classification was derived from the American Society of Anesthesiologists physical status classification system as shown in Table 3.1. All
patients included in the chart review were ASA class I, II, or III. Patients who met the emergency classification were also included provided they met other inclusion criteria.

Adapted from Marley, Calabrese, and Thompson, 2014, table 19-15.

Postoperative pain data was obtained by comparing the morphine equivalency doses between the groups. Morphine equivalency doses were calculated from the doses listed in table 3.2 and converted to micrograms per kilogram. Postoperative pain data was obtained throughout the intraoperative and postoperative periods. Intraoperative data was included because many pain medications given intraoperatively have duration of action times that extend into the postoperative phase of care.

Adapted from McAuley, 2013

Postoperative nausea and vomiting rates were obtained by comparing the number of administration of antiemetic medications. The preoperative phase of care was included due to many surgical patients being administered antiemetics prophylactically.

Total anesthesia time was compared between the two sample groups to determine if the anesthetic technique cost was significantly different. As previously stated, some research suggests that regional anesthesia has a longer preparation time compared to general anesthesia alone. The anesthesia provider administering the regional anesthesia is also more costly compared to preoperative staff.
CHAPTER IV
ANALYSIS OF DATA

The comparison groups were composed of 24 patient charts, with 12 charts accounting for each group. The first group included patients that received a peripheral nerve block. The second group included those patients that received general anesthesia only.

Student t-tests were used to evaluate whether the regional anesthesia group had lower rates of PONV, decreased opioid medication administration, decreased length of stay in PACU, and to compare total anesthesia time between the two groups. The student $t$ was used because two groups were being compared with a normal distribution and had similar standard deviations. A $p$ value of $\leq 0.05$ was considered to be of statistical significance.

GraphPad Prism software was used for all statistical calculations. The specific statistical figures calculated included the mean, standard deviation, and confidence interval. The GraphPad Prism website was used for data input.

The total anesthesia time of each group was first compared. The total anesthesia time for the regional group had a mean of 133.33 minutes while the general anesthesia group had a mean time of 128.83 minutes. Using the student $t$ test to compare the two groups, there was no significant difference in total anesthesia time with $p$ value $= 0.84$.

Pain medication administration was compared between the two groups using the morphine equivalency doses in Table 3.2. The medication dosage was converted to micrograms (mcg) per kilogram (kg). The mean of the regional
group was 210.85 mcg/kg while the mean for the general group was 256.18 mcg/kg. The student *t* test was used to compare the two groups. There was no significant difference in opioid administration between the groups with the *p* value = 0.31.

The number of antiemetic doses was compared between the two groups. The regional group had a mean of 1.75 doses while the general group had a mean of 1.33 doses. The student *t* test was used to compare the groups. The *p* value = 0.38 with no significant difference between the groups.

The time in PACU was then compared between the groups. The time from PACU admit until ready for discharge was used for comparison. The regional group had a mean of 37.5 minutes while the general group had a mean of 36.3 minutes. The student *t* test was used for comparison. With the *p* value = 0.79, there was no significant difference in PACU length of stay between the groups.
CHAPTER V
SUMMARY

This capstone project compared outcomes between two groups using a retrospective chart review. Outcomes that were compared include postoperative pain, PONV, total anesthesia time, and PACU discharge times. The first group was composed of patients who received regional anesthesia to include an interscalene, supraclavicular, or axillary peripheral nerve block. The second group was composed of patients who received general anesthesia only or a failed peripheral nerve block.

Inclusion criteria were patients 35-65 years old and undergoing orthopedic surgery of the upper extremity, patient classification I, II, or III. Patients who met emergency classification were included in chart review. Multisystem trauma patients were excluded from the review. Patients that received a continuous nerve block via indwelling catheter were also excluded.

Postoperative pain was assessed using morphine equivalency doses listed in Table 3.2 and converted to micrograms per kilogram. Postoperative nausea and vomiting was compared by antiemetic medication administration. PACU ready for discharge times were used to compare length of stay in PACU.

Conclusions

There were no significant differences found between the two groups with regard to postoperative pain, PONV, total anesthesia time, or PACU time. This chart review was limited to the immediate postoperative time only and did not compare outcomes beyond discharge from PACU. This finding has clinical
implications for the anesthesia provider, especially the provider in a rapid
turnover environment such as ambulatory surgery centers.

In those patients who either refuse peripheral nerve block or cannot
receive the nerve block due to contraindications, the length of stay in PACU will
not be extended. Likewise, patients who are good candidates for regional
anesthesia but are poor candidates for general anesthesia will have a similar
length of stay in PACU.

Recommendations for Future Study

There are several recommendations for future studies to build on this
retrospective chart review. This retrospective chart review was limited to the
immediate postoperative period in the PACU. One recommendation for future
study is to extend the review period beyond the immediate postoperative period.
This may capture statistically significant differences in regards to postoperative
pain management and PONV.

Extending the review period beyond PACU may show significant
differences in relation to the economic impact as well. One reason for this is
admitted patients in the general anesthesia group received a PCA pump upon
transfer from the PACU. Comparing the cost of medication in the PCA pump to
the medication used in the nerve block may be significantly different.

As this chart review demonstrated, there were no significant differences in
total anesthesia time between groups. Some providers perceive the time taken
to perform the nerve block as a deterrent. For the regional group in the chart
review, the sum on the peripheral nerve block time and the general anesthesia
time was used to compare anesthesia times. A recommendation for future study is to gather data on the regional nerve block performance time. This may serve as further evidence that performing a peripheral nerve block does not significantly add time to the anesthesia plan.

INSTITUTIONAL REVIEW BOARD NOTICE OF COMMITTEE ACTION
NOTICE OF COMMITTEE ACTION

The project has been reviewed by the University of Southern Mississippi Institutional Review Board in accordance with Federal Drug Administration regulations (21 CFR 20, 111), Department of Health and Human Services (45 CFR Part 46), and university guidelines to ensure adherence to the following criteria:

- The risks to subjects are minimized.
- The risks to subjects are reasonable in relation to the anticipated benefits.
- The selection of subjects is equitable.
- Informed consent is adequate and appropriately documented.
- Where appropriate, the research plan makes adequate provisions for monitoring the data collected to ensure the safety of the subjects.
- Where appropriate, there are adequate provisions to protect the privacy of subjects and to maintain the confidentiality of all data.
- Appropriate additional safeguards have been included to protect vulnerable subjects.
- Any unanticipated, serious, or continuing problems encountered regarding risks to subjects must be reported immediately, but not later than ‘0 days following the event. This should be reported to the IRB Office via the “Adverse Effect Report Form”.
- If approved, the maximum period of approval is limited to twelve months.

Projects that exceed this period must submit an application for renewal or continuation.

PROTOCOL NUMBER: 15081104
PROJECT TITLE: Does the Use of a Regional Nerve Block Decrease the Incidence of Post Operative Nausea and Vomiting, Decrease Pain Scores, or Decrease Discharge Time Compared to General Anesthesia Alone?
PROJECT TYPE: New Project
RESEARCHER(S): Donald Lane Whitney
COLLEGE/DIVISION: College of Nursing
DEPARTMENT: Advanced Practice
FUNDING AGENCY/SPONSOR: N/A
IRB COMMITTEE ACTION: Expedited Review Approval
PERIOD OF APPROVAL: 08/14/2015 to 08/13/2016

Lawrence A. Hosman, Ph.D.
Institutional Review Board
